- 19. If the infiltration continues at full capacity (i.e., the ponding effect continues throughout the period), the cumulative infiltration at the end of the period can be computed from the same equation of step 12 plotted in Figure 2.19. For t = 50 min or 0.83 hr, F = 1.60 in.
- **20.** Depression storage will reduce by 0.2 in. equal to  $(i\Delta t \Delta F)$ .
- F. Sixth and seventh rainfall periods
  - 21. Computation continues similar to the fourth period by the application of the equation of step 12 as shown in Table 2.19.

# 2.14 HEC'S NONLINEAR LOSS-RATE FUNCTION APPROACH FOR DIRECT RUNOFF

The Hydrologic Engineering Center (HEC) of the U.S. Army Corps of Engineers has used the term *loss* for the precipitation not available to direct runoff and has indicated that the rate of loss is related nonlinearly to the rainfall intensity and a *loss-rate function* that decreases with increased ground wetness. The HEC studies indicated that a fairly definite quantity of water loss by interception and infiltration is required to satisfy initial moisture deficiencies before runoff can occur. An allowance for this initial loss or initial abstraction is made according to various antecedent soil moisture conditions. After the initial abstraction, the loss takes place at the following rate, which does not exceed the amount of precipitation for any time interval:

$$f = Kp^E \qquad [LT^{-1}] \tag{2.47a}$$

with

$$K = K_0 C^{-0.1L} \qquad [dimensionless]$$
 (2.47b)

where

f = loss rate, in. or mm per hour

K = loss rate function

p = rainfall intensity, in. or mm per hour

E = exponent ranging between 0.3 and 0.9, with a frequent value of 0.7

 $K_0 =$ loss coefficient at start of a storm

C =coefficient controlling the rate of decrease of the loss-rate function

L = accumulated loss during the storm, in. or mm

A typical plot for the loss-rate function is shown in Figure 2.20. The loss-rate coefficients are determined from the rainfall and runoff data. The HEC has developed a loss-rate optimization program for this purpose (HEC, 1973).

## EXAMPLE 2.17

Determine the rainfall excess for successive periods for the storm of Example 2.16 by the loss-rate function approach. Assume that Figure 2.20 applies for the loss-rate function. Use E=0.7.

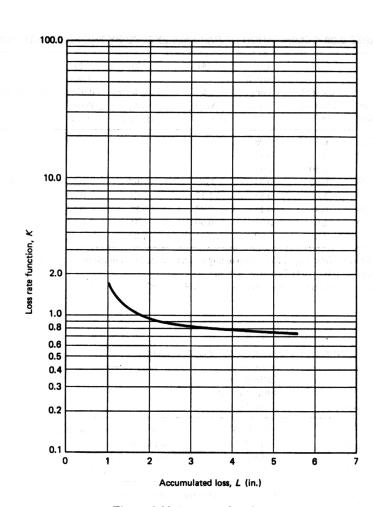

Figure 2.20 Loss-rate function.

### **SOLUTION**

ain fall Excess
(in.)
ol. 3—col. 6)

- 1. Initial accumulated loss from Figure 2.20 is 1.0 in.
- 2. Assuming a uniform distribution of the rain within 10-min observation periods, the rainfall of the first 25 min will be abstracted in the initial loss of about 1.0 in., as follows:

0-10 min 0.5 
$$(\frac{10}{60}) = 0.08$$
 in.  
10-20 min 2  $(\frac{10}{60}) = 0.33$  in.  
20-25 min 6.5  $(\frac{5}{60}) = 0.54$  in.  
0.95 in.

3. The direct runoff will appear after 25 min. The computation is shown in Table 2.20.

# 2.15 THE NRCS APPROACH FOR DIRECT RUNOFF

By studying the infiltration behavior of different types of soils, the Natural Resources Conservation Service (formerly SCS) developed a method of computing the direct runoff

<sup>&</sup>lt;sup>a</sup>Reproduced from U.S. Soil Conservation Service (1986).

resulting from a rainfall storm (U.S. SCS, 1972). The factors affecting infiltration are: hydrologic soil group, type of land cover, hydrologic condition and antecedent (pre-storm) moisture condition, and cropping practice in the case of cultivated agriculture land. Each of these factors is subdivided into many classes. Hydrologically, soils are assigned four groups on the basis of intake of water on bare soil when thoroughly wetted, as shown in Table 2.21. With urbanization the soil profile is disturbed considerably. The group classification can be based on the texture of disturbed soil.

Type of land cover, such as bare soil, vegetation, impervious surface, and so on, establishes runoff production potential. Important cover types for urban areas, cultivated agriculture lands, other agriculture lands, and arid rangelands are given in Table 2.22. Cultivated agricultural lands are further subdivided by treatment or cropping practice, such as straight row, contoured, and contoured and terraced. The hydrologic conditions reflect the level of land management. Hydrologically poor conditions represent a state of land use that will provide higher runoff compared to good conditions. The antecedent moisture condition (AMC) is the index of the soil condition with respect to runoff potential before a storm event. It has three categories as shown in Table 2.23.

<sup>&</sup>lt;sup>b</sup> For example,  $f = (1.7)(6.5)^{0.7} = 6.30$ .

c (Column 5)(duration in hours): i.e., (6.3)(5/60) = 0.53.

	III	Saturated soils; heavy rainfall or ligh	t rainfall with low temperatures have occurred in the last 5 days

The NRCS (SCS) has evolved a system of curve numbers. A distinct curve number (CN) is assigned on the basis of the combination of the factors above. Table 2.22 gives curve numbers for antecedent moisture condition II. Table 2.24 provides conversion of CNs to other conditions. For an area with many different subareas, the composite CN is determined by adding the product of CN and respective area and dividing by the total area.

The NRCS runoff equation is

$$Q = \frac{(P - 0.2S)^2}{(P + 0.8S)}$$
 [L] (2.48)

where

Q = accumulated runoff, in. or mm depth over the drainage area

P = accumulated rainfall depth, in. or mm

S =potential maximum retention\* of water by the soil, in. or mm

The potential maximum retention, S, is related to the curve number, CN, by the following relation:

$$CN = \frac{1000}{10 + S}$$
 [unbalanced] (2.49)

Thus, once a curve number is ascertained from Tables 2.22 and 2.24 for the known conditions, the direct runoff can be computed from eqs. (2.48) and (2.49). The TR-55 (SCS, 1986) contains a graph and a table that solve eq. (2.48) directly. The tabular solution is reproduced in Table 2.25 for a certain range of CNs and rainfall values.

To use the method for sequential rainfall, the intensity is converted to the rainfall depth for each period of sequence and accumulated to the end of each period. From the

<sup>&</sup>lt;sup>a</sup>Interpolate the values shown to obtain runoff depths for CNs or rainfall amounts not shown. Source: U.S. Soil Conservation Service (1986).

<sup>\*</sup>This is mostly the infiltration. The term is distinct from the surface retention, which does not include the infiltration.

accumulated rainfall to the end of successive rain periods, the accumulated direct runoff or rainfall excess is derived for each time period using the NRCS equation (2.48). The accumulated direct runoff is then converted to the increments of the runoff.

## EXAMPLE 2.18

Determine the direct runoff (rainfall excess) for successive 10-min periods of the storm of Example 2.16. The soil in the basin belongs to hydrologic group B. The basin is mostly wooded in good hydrologic condition. The saturated soil condition (condition III) exists in the basin.

### SOLUTION

- 1. For given hydrologic characteristics and for moisture condition II, CN = 55, from Table 2.22.
- 2. Corresponding CN = 75 for condition III, from Table 2.24.
- 3. Computations for accumulated rain and runoff are given in Table 2.26.

## 2.16 INFILTRATION-INDEX APPROACH FOR DIRECT RUNOFF

The index approach is the simplest procedure to estimate the total volume of storm runoff. The object of this method is to obtain a coefficient that may be applied to an entire rain period, or to an entire storm if it is made up of several rain periods, to arrive at an estimate of the direct runoff (Cook, 1946). Three types of indices are common: (1) the  $\phi$  index, which represents a level (horizontal line) of intensity that divides the rainfall intensity diagram in such a manner that the depth of rain above the index line is equivalent to surface runoff depth over the basin, as illustrated in Figure 2.21; (2) the  $f_{av}$  index, which indicates the average rate of infiltration during a period in which the rainfall intensity is equal to or more than the infiltration capacity,  $f_p$ ; and (3) the W index, which is a mean of  $f_{av}$  when it varies across a watershed. The value of W for a rain occurring after the watershed is wetted and the infiltration capacity is reduced to the minimum is known as the  $W_{min}$  index.

The  $\phi$  index is the simplest of these indices. For its determination, the rainfall due to a storm is measured and the amount of runoff is obtained from the corresponding direct
